ABSTRACT

In this paper, we propose a new method for the recovery of a sparse signal from few linear measurements using a reference signal as side information. Modeling the signal coefficients with a double Laplace mixture model, and assuming that the distribution of the components of the prior information differs slightly from the unknown signal, the problem is formulated as a weighted \(\ell_1\) minimization problem.

We derive sufficient conditions for perfect recovery and show that our method is able to significantly reduce the number of measurements required for reconstruction. Numerical experiments demonstrate that the proposed approach outperforms the best algorithms for compressed sensing with prior information and is robust in imperfect scenarios.

Index Terms—Compressed sensing, mixture models, side information, sparse recovery, weighted \(\ell_1\) minimization.

1. INTRODUCTION

The theory of compressed sensing (CS) has proved that a \(k\)-sparse signal \(x^* \in \mathbb{R}^n\) (i.e., it has at most \(k \ll n\) nonzero entries) can be recovered from a small collection of linear measurements \(y = Ax^* \in \mathbb{R}^m\) \((m \ll n)\) via the constrained \(\ell_1\) minimization, that consists in selecting the element which is compatible with the observations which has minimal \(\ell_1\)-norm.

In this paper, we consider the problem of compressed sensing with side information as addressed in [1]. More precisely, we are interested in recovering the high dimensional signal \(x^*\) from \(y\), with the additional information that \(x^*\) is similar to a reference signal \(w\). This problem arises in several situations, as in compressive image sampling [2, 3], where the spatial and temporal correlation within image/video is exploited. Also in sensor/camera networks [4, 5, 6], the signals acquired by close sensors are similar and can be used as prior information to reduce the number of measurements needed for reconstruction. We refer to [1] for an overview of the applications.

In [1], the authors propose to solve the following optimization problem

\[
\min_{x \in \mathbb{R}^n} \|x\|_1 + \gamma \|x - w\|_p^p \quad \text{s.t.} \quad y = Ax
\]

with \(p \in \{1, 2\}\) and \(\gamma > 0\), referred as \(\ell_1-\ell_1\) minimization, and \(\ell_1-\ell_2\) minimization, respectively. Moreover, sufficient conditions on the number of measurements for perfect reconstruction are derived. In particular, it is shown that the number of measurements required by \(\ell_1-\ell_1\) minimization is much smaller than that obtained using classical CS.

The use of prior information as a tool to reduce the number of measurements required for signal reconstruction has appeared in CS literature [1, 7, 8] also with different assumptions. In [7], the authors employ as prior information an estimate \(T\) of the support of \(x^*\) and propose a truncated \(\ell_1\)-minimization problem, i.e. the minimization of

\[
\min \|x_{T^c}\|_1 \quad \text{s.t.} \quad y = Ax^*.
\]

It should be noticed that (2) can be adapted to our problem using \(T = \text{supp}(w)\) (Mod-CS, [7]). Another piece of literature [8, 9] considers a weighted \(\ell_1\)-minimization with weights \(w_i = -\log p_i\) where \(p_i\) is the probability that \(x_i = 0\). It should be remarked that in our setting \(p_i\) is not available.

In this paper, we propose a new weighted \(\ell_1\) minimization, which we call 2LMM-CS. The fundamental idea is to use a good generative model for sparse and compressible vectors [10]. For this purpose, we use a Laplace mixture model (2LMM) as the parametric representation of the prior distribution of the signal coefficients. Because of the partial symmetry of the signal sparsity, we know that each coefficient should have one out of only two distributions: a Laplace with small variance with high probability and a Laplace with large variance with low probability. This model has been shown effective to represent sparse signals or compressible signals in [11]. Then, we cast the estimation problem as a non convex optimization problem that incorporates the parametric representation of the signal. However, the optimization problem turns out to be computationally hard. Assuming that...
2. SUPPORT DETECTION AND SPARSE SIGNAL ESTIMATION VIA 2-LMM

2.1. Modeling sparse or compressible vectors

We consider a two-state mixture model as a prior that describes our knowledge about the sparsity of the signal $x^*$. Because of the partial symmetry of the signal sparsity, we consider the case in which $x$ is a random variable of the form

$$x_i = z_i u_i + (1 - z_i) v_i \quad i \in [n]$$

where $u_i$ are identically and independently distributed (i.i.d.) according to Laplace(0, $\alpha$), $v_i$ are i.i.d. as Laplace(0, $\beta$) and $z_i$ are i.i.d. Bernoulli random variables with probability mass function $f(z_i = 1) = 1 - p$, with $p = K/n \ll 1/2$, $\alpha \approx 0$, $\beta \gg 0$, and $K \geq k$ is an estimate of the signal sparsity, in order to ensure that we have few large coefficients. This mixture model is completely described by three parameters: the sparsity ratio $p \ll 1/2$ (or $K$, equivalently), $\alpha$ that is expected to be small and $\beta > \alpha$ if the signal is sparse. It should be noticed that vectors generated from this distribution are typically compressible, according to definition [10].

2.2. Estimation using 2-LMM generative model

Let $\Theta = (\alpha, \beta)$ and consider the logarithm of the conditional distribution: $L(x; \Theta) := \log[f(x|y; \Theta)]$

**Proposition 1.** Given $y, A, \Theta$, $L(x; \Theta) = \begin{cases} J(x, \pi; \Theta) - \sum_{i=1}^n H(\pi_i) & \text{if } y = Ax \\ +\infty & \text{if } y \neq Ax \end{cases}$ (3)

where

$$J(x, \pi; \Theta) = \sum_{i=1}^n \left[ \frac{\pi_i|x_i|}{\alpha} + \pi_i \log \alpha - \pi_i \log(1 - p) + \frac{(1 - \pi_i)|x_i|}{\beta} + (1 - \pi_i) \log \beta - (1 - \pi_i) \log p \right],$$

$$\pi_i = \pi_i(x) = \mathbb{E}[z_i|x; \Theta] = f(z_i = 1|x; \Theta) \text{ and } H \text{ is the natural entropy function.}$$

The proof is obtained as a simple consequence of Jensen’s inequality and using the logarithm properties.

**Corollary 1.** The following optimization problems are equivalent

$$\max_{x \in \mathbb{R}^n} L(x; \Theta) \quad (5)$$

$$\min_{x \in \mathbb{R}^n} \min_{\pi \in \Sigma_{n-K}} J(x, \pi; \Theta) - \sum_{i=1}^n H(\pi_i) \quad \text{s.t. } Ax = y \quad (6)$$

Given $y, A$, we consider the following modified optimization problem:

$$\min_{x \in \mathbb{R}^n} \min_{\pi \in \Sigma_{n-K}} J(x, \pi; \Theta) - \sum_{i=1}^n H(\pi_i) \quad \text{s.t. } Ax = y \quad (7)$$

that introduces the constraint $\pi \in \Sigma_{n-K}$, which allows to take into account that we seek a sparse solution with a guess of the sparsity level $K$. It should be noted that there is not a closed form solution to problem (7). However, partial minimization of function in (7) with respect to $\pi$ leads to the following expression.

**Lemma 1.** Let

$$\hat{\pi} = \hat{\pi}(x, \Theta) = \arg \min_{\pi \in \Sigma_{n-K}} J(x, \pi; \Theta) - \sum_{i=1}^n H(\pi_i)$$

then

$$\hat{\pi} = \sigma_{n-K} \left( \frac{1}{1 + \frac{\alpha}{\beta} p^{1 - p} e^{e^{w_i}|x_i| \left( \frac{\beta}{\alpha} - 1 \right)}} \right). \quad (8)$$

where

$$\sigma_j(u) = \min \{ z \in \mathbb{R}^n : \|z - v\|_2 \}$$

is a thresholding operator which acts on $v$ by keeping the $j$ biggest elements in absolute value and setting the others to zero.

3. COMPRESSED SENSING WITH PRIOR INFORMATION VIA 2LMM

Let us consider the optimization problem in (7) and suppose $\alpha$ and $\beta$ are fixed and $0 \approx \alpha < \beta$. Assuming that the distribution of the signal coefficients of $w$ is similar to that of $x^*$, we fix

$$\pi_i = \pi_i(w) = f(z_i = 1|w, \alpha, \beta) = \frac{1}{1 + \frac{\alpha}{\beta} p^{1 - p} e^{w_i|z_i| \left( \frac{\beta}{\alpha} - 1 \right)}}.$$  \quad (9)

and $\hat{\pi}(w) = \sigma_{n-K}(\pi_i(w))$. Let $T^c = \text{supp}(\hat{\pi})$ and $T = \{ i \in [n] : \hat{\pi}_i = 0 \}$. We have $\hat{\pi}_i = \pi_i, \forall i \in T^c$ and $\hat{\pi}_i = 0, \forall i \in T$.

It should be noticed that, given $\alpha, \beta, \pi$, minimization of (7) over $x$ is equivalent to computation of

$$\min_{x \in \mathbb{R}^n} \sum_{i \in T} \omega|x_i| + \sum_{i \in T^c} (\pi_i + (1 - \pi_i)\omega)|x_i|,$$ \quad (10)

s.t. $Ax = y$ with $\omega = \alpha/\beta$. 

The distribution of the nonzero coefficients is similar to that of unknown signal, the estimation problem is simplified to a weighted $\ell_1$-minimization.

We show that under certain conditions the number of measurements required for reconstruction can be significantly reduced compared to the techniques used in literature before. Finally, numerical experiments show that 2LMCS achieves excellent performance in several situations and outperforms the state of the art on this subject.
Definition 1. Let $\Lambda \subset \{1, \ldots, n\}$ with $|\Lambda| = k \leq K$, $\omega \in [0, 1]$, $\pi \in [0, 1]^n$, and $T = \{i \in [n] : [\sigma_{n-K}(\pi)]_i = 0\}$. A matrix $A \in \mathbb{R}^{m \times n}$ is said to satisfy the non-uniform weighted ($\omega, \pi, K, \Lambda$)-NSP if for any $h \in \text{Ker}(A) \setminus \{0\}$, we have

$$
\omega \|h_\Lambda\|_1 + (1 - \omega) \sum_{i \in S} \pi_i |h_i| < \sum_{i \in \Lambda^c} (\pi_i + (1 - \pi_i)\omega) |h_i|
$$

where $S = (\Lambda \cap T^c) \cup (\Lambda^c \cap T)$.

Definition 1 is non-uniform and depends on a fixed set $\Lambda$. As will be clear in next results, this condition is necessary and sufficient for the recovery of a sparse vector supported on $\Lambda$ using (10). The following definition, instead, considers a weighted uniform null space property, which is a necessary and sufficient condition for the recovery of all $k$-sparse vectors from compressive measurements via (10).

Definition 2. Let $\omega \in [0, 1]$ and $\pi \in [0, 1]^n$. A matrix $A \in \mathbb{R}^{m \times n}$ is said to satisfy the weighted ($\omega, \pi, K$)-NSP (Null Space Property) of order $k$ if it satisfies the non-uniform weighted ($\omega, \pi, K, \Lambda$)-NSP (Null Space Property) for all $\Lambda \subset [n]$ with $|\Lambda| \leq k$.

Theorem 1. The weighted $\ell_1$-minimization in (10) uniquely recovers every $k$-sparse vector $x^*$ from measurements $y = Ax^*$ if and only if $A$ satisfies the ($\omega, \pi, K$)-NSP of order $k$.

Theorem 2. Let $\Lambda \subset [n]$ with $|\Lambda| \leq k \leq K$, $\omega \in [0, 1]$, $\pi \in [0, 1]^n$, and $T = \{i \in [n] : [\sigma_{n-K}(\pi)]_i = 0\}$ and $A \in \mathbb{R}^{m \times n}$ be a matrix whose entries are i.i.d. Gaussian random variables with zero-mean and unit variance. Then $A$ satisfies non-uniform weighted ($\omega, \pi, K, \Lambda$)-NSP with probability greater than $1 - \epsilon$ if the following condition holds

$$
m \geq K + O\left(\frac{1}{\epsilon^2} \frac{1}{\sqrt{\ln \frac{m}{n}}} \frac{\ln(\epsilon n/k)}{1 + \frac{1}{2} \ln(\epsilon n/k)} \ln(\epsilon n/k)\right),
$$

where $r(w)$ is the non-increasing rearrangement of $w$, i.e., $r(w) = (|w_{i_1}|, \ldots, |w_{i_n}|)$ with $|w_{i_\ell}| \geq |w_{i_{\ell+1}}|$ for all $\ell = 1, \ldots, n - 1$.

It should be noticed if $\frac{r(w)_K}{|w|_K} \neq 0$, being $\alpha \approx 0$ the second term is very small, suggesting that just $K$ measurements are sufficient for recovery.

4. NUMERICAL EXPERIMENTS

We compare 2LMM-CS with classical CS and the best algorithms for CS with side information known in literature: Mod-CS, $\ell_1-\ell_1$ and $\ell_1-\ell_2$ minimization (see the Sec. I for an overview of these methods).

As a first experiment, we employ the same setting analyzed in [1]. A signal $x^*$ of length $n = 1000$ is generated with sparsity $k = 70$. The nonzero elements of $x^*$ are drawn from a standard Gaussian distribution. The prior information $w$ is obtained $w = x^* + z$, where $z$ is a 28-sparse signal, whose nonzero elements are drawn from a Gaussian distribution with standard deviation 0.8. The vector $z$ is such that $|\text{supp}(z) \cap \text{supp}(x^*)| = 22$ and $|\text{supp}(z) \cap \text{supp}(x^*)^c| = 6$. The resulting vector $w$ differs significantly from the true vector $x^*$ and the relative distance is $\|x^* - w\|_2/\|x^*\|_2 = 0.502$. The sensing matrix $A$ with $m$ rows and $n$ columns is sampled from the Gaussian ensemble with zero mean and variance $1/m$. In $\ell_1-\ell_1$ and $\ell_1-\ell_2$ minimization $\gamma = 1$, as employed in [1]. For CS-2LMM the mixture parameters have been set as follows: $\alpha = 10^{-4}$, $\beta = 10$, $K = |\text{supp}(w)| = 76$. Instead Mod-CS uses as prior information $T = \text{supp}(w)$. Fig. 1 shows the empirical recovery success rate, averaged over 50 experiments, as a function of the number of measurements $m$. For a fixed $m$, we mean the success when a given algorithm reconstructs the signal $x^*$ with a relative error smaller than $10^{-2}$. It should be noticed that $\ell_1-\ell_1$ minimization achieves the best performance, if compared with CS, Mod-CS and $\ell_1-\ell_2$ minimization. It requires $m \geq 140$ measurements to recover perfectly the signal with a probability larger than 0.95. It should be appreciated that 2LMM-CS reduces this number to 80.
We now investigate the performance of the algorithms in imperfect scenarios. We consider signal $x^\star$ and $z$ generated as in the previous experiment. The prior information $w$ is obtained by $w = x^\star + z + \eta$, where $\eta$ is a gaussian noise with standard deviation $10^{-3}$. The resulting relative error is $\|w - x\|/\|x\| = 0.6489$. The sensing matrix $A$ is sampled from the Gaussian ensemble with zero mean and variance $1/m$. Mod-CS uses as prior information the set $T$ of the 123 largest components in absolute value of vector $w$. For CS-2LMM the mixture parameters have been set as follows: $\alpha = 10^{-4}$, $\beta = 10$, and $K = 123$. Fig. 2 depicts the empirical recovery success rate, averaged over 50 experiments, as a function of the number of measurements $m$. It should be noticed that 2LMM-CS achieves the best performance and the condition for perfect reconstruction is $m \geq 125$. Mod-CS has the second best performance requiring $m \geq 225$ measurements, followed by classical CS with $m \geq 325$. In this setting, $\ell_1-\ell_1$ minimization and $\ell_1-\ell_2$ minimization require $m \approx 500$, behaving poorly in this context.

Finally, we consider the case in which $x^\star$ is generated as above and the prior information is a blurred version of $x^\star$. More precisely, $w$ is obtained from $x^\star$ by applying a blur filter of order 3: $w_i = (x_{i-1}^\star + x_i^\star + x_{i+1}^\star) / 3$. The relative error is $\|w - x\|/\|x\| = 0.8147$. Figure 3 emphasizes that 2LMM-CS achieves the best performance also in this setting, requiring about 175 measurements for reconstruction. Instead, Mod-CS, CS and $\ell_1-\ell_1$ minimization need a number of measurements for reconstruction dramatically larger ($m \geq 325$) than 2LMM-CS. Moreover $\ell_1-\ell_1$ has the same performance of CS, bringing no significant benefits in this case. Instead, the $\ell_1-\ell_2$ minimization is not able to perform the recovery with a number of measurements smaller than 425.

5. CONCLUDING REMARKS

In this paper, we have shown a new method to efficiently perform sparse recovery in presence of side information. Combining MAP estimation with the parametric representation of the signal with a Laplace mixture model, we have formulated the problem as a weighted $\ell_1$-minimization. The main theoretical contribution includes the derivation of sufficient conditions for perfect recovery. Numerical simulations show that these new algorithms reduce the number of measurements required for reconstruction and are robust for several models of prior information.
